**Abstract.** The emission of nitric oxide (NO) by soils (SNOx) is an important source of oxides of nitrogen ( $\text{NO}_x = \text{NO} + \text{NO}_2$ ) in the troposphere, with estimates ranging from 4 to 21 Tg of nitrogen per year. Previous studies have examined the influence of SNOx on ozone ( $\text{O}_3$ ) chemistry. We employ the ECHAM5/MESy atmospheric chemistry model (EMAC) to go further in the reaction chain and investigate the influence of SNOx on lower tropospheric  $\text{NO}_x$ ,  $\text{O}_3$ , peroxyacetyl nitrate (PAN), nitric acid ( $\text{HNO}_3$ ), the hydroxyl radical (OH) and the lifetime of methane ( $\tau_{\text{CH}_4}$ ). We show that SNOx is responsible for a significant contribution to the  $\text{NO}_x$  mixing ratio in many regions, especially in the tropics. Furthermore, the concentration of OH is substantially increased due to SNOx, resulting in an enhanced oxidizing efficiency of the global troposphere, reflected in a  $\sim 10\%$  decrease in  $\tau_{\text{CH}_4}$  due to soil NO emissions. On the other hand, in some regions SNOx has a negative feedback on the lifetime of  $\text{NO}_x$  through  $\text{O}_3$  and OH, which results in regional increases in the mixing ratio of  $\text{NO}_x$  despite lower total emissions in a simulation without SNOx. In a sensitivity simulation in which we reduce the other surface  $\text{NO}_x$  emissions by the same amount as SNOx, we find that they have a much weaker impact on OH and  $\tau_{\text{CH}_4}$  and do not result in an increase in the  $\text{NO}_x$  mixing ratio anywhere.

## 1 Introduction

Nitric oxide (NO) in the soil is produced by the microbial processes of nitrification and denitrification (Firestone and Davidson, 1989). The NO emission originates from a natural pool of nitrogen and a fraction from fertilizer application (Yienger and Levy II, 1995; Stehfest and Bouwman, 2006). The estimates of NO emitted yearly by soils (hereafter called SNOx) ranges from 4 to 21 Tg(N) (Yienger and Levy II, 1995; Davidson and Kinglerlee, 1997, and references therein). NO reacts rapidly with other atmospheric compounds, establishing an equilibrium between NO and nitric dioxide ( $\text{NO}_2$ ). These two species are frequently referred to the oxides of nitrogen ( $\text{NO}_x$ ). Through reactions, deposition and stomatal uptake directly within the vegetation layer not all NO emitted by the soil escapes the canopy layer as  $\text{NO}_x$  (Yienger and Levy II, 1995; Ganzeveld et al., 2002b). SNOx is topped by the anthropogenic combustion of fossil fuels ( $20\text{--}24 \text{ Tg(N) yr}^{-1}$ ) (Denman et al., 2007) and is comparable to the production of  $\text{NO}_x$  from lightning and biomass burning, but especially in remote continental regions of the mid- and low-latitudes SNOx is the dominant source of  $\text{NO}_x$ . In this work SNOx refers to the flux from the canopy to the atmosphere. The fraction of  $\text{NO}_x$  that reaches the atmosphere reacts as a catalyst for production of ozone ( $\text{O}_3$ ), an important greenhouse gas. This  $\text{O}_3$  production is driven by the oxidation of carbon monoxide (CO) and volatile organic compounds (VOC), if the concentration of NO is higher than about  $5\text{--}30 \text{ pmol mol}^{-1}$  (Brasseur et al., 1999). The unit used in this work is the molar (or “volume”) mixing ratio as mol tracer per mol air (e.g.  $\text{pmol mol}^{-1}$ ). Atmospheric  $\text{NO}_x$  is also involved in the production of the hydroxyl radical (OH), which is responsible for the oxidation and depletion

(steinkam@mpch-mainz.mpg.de)

of methane ( $\text{CH}_4$ ), another greenhouse gas. Beyond these climate related issues, high  $\text{NO}_x$  and  $\text{O}_3$  mixing ratios also have a direct impact on human health and on the vegetation (Sitch et al., 2007).  $\text{NO}_x$  is removed from the atmosphere by reaction with hydroxyl radicals (OH) or oxidation to dinitrogen pentoxide ( $\text{N}_2\text{O}_5$ ) and subsequent deposition as nitric acid ( $\text{HNO}_3$ ). It can also react with organic tracers to form peroxy nitrates, mainly peroxyacetyl nitrate (PAN), which, once it is lifted to higher altitudes, can be transported over large distances releasing  $\text{NO}_x$  when it is transported back downward again.

Previous model studies of the influence of SNO<sub>x</sub> on atmospheric chemistry mainly focused either on the  $\text{NO}_x$  source itself, on  $\text{O}_3$ , mostly on a regional scale. Ganzeveld et al. (2002a,b) investigate two different modeling approaches of the role of canopy processes on the effective exchange of  $\text{NO}_x$  between the canopy and atmosphere. They concluded that the application of the big leaf approach with a separate treatment of dry deposition and biogenic emissions, in which the canopy reduction factor accounts for the fraction of these emission that escapes the canopy, provides a reasonable first order estimate of  $\text{NO}_x$  canopy top fluxes. Jaeglé et al. (2005) examined the global partitioning of  $\text{NO}_x$  sources using inverse modelling and the space-based  $\text{NO}_2$  column derived by GOME (Global Ozone Monitoring Experiment). Their a posteriori SNO<sub>x</sub> ( $8.9 \text{ Tg(N) yr}^{-1}$ ) is 68% greater than their a priori SNO<sub>x</sub> ( $5.3 \text{ Tg(N) yr}^{-1}$ ). Based on this, Jaeglé et al. (2005) suggest that the influence of SNO<sub>x</sub> on background  $\text{O}_3$  could be underestimated in current chemistry transport models (CTMs). Bertram et al. (2005) come to a similar conclusion by inverse modelling using another satellite sensor (SCIAMACHY) above the Western United States, computing an underestimation of 60%. Delon et al. (2008) modelled higher  $\text{O}_3$  concentrations with higher SNO<sub>x</sub> above Western Africa. For Europe, Simpson (1995) found that SNO<sub>x</sub> hardly has any influence on controlling the  $\text{O}_3$  mixing ratio. Isaksen and Hov (1987) already investigated the influence of changes in the emission intensity of different relevant trace gases on the oxidizing efficiency through an increase in OH concentration with increased  $\text{NO}_x$  emissions, but they did not consider SNO<sub>x</sub> separately in their assessment. Fuglestad et al. (1999) demonstrate the importance of the geographical region of  $\text{NO}_x$  sources for the changes in the ozone concentration and the oxidizing efficiency.

In this study, we take these analysis a step further and follow the reaction chain from SNO<sub>x</sub> through  $\text{O}_3$  and OH to its global influence on the oxidizing efficiency of the atmosphere. To do so, we compare two model runs with a state-of-the-art 3-D global chemistry climate model. One is a simulation with all relevant emissions and reactions (BASE), and the second simulation is without SNO<sub>x</sub> (NOBIONO = “No biogenic NO”). We expect a considerable influence of SNO<sub>x</sub> on the mixing ratios and distribution of related global tropospheric trace gases ( $\text{NO}_x$ , PAN,  $\text{HNO}_3$ ,  $\text{O}_3$  and OH). Furthermore the global oxidizing efficiency, indicated by the lifetime

of  $\text{CH}_4$  ( $\tau_{\text{CH}_4}$ ), is expected to decrease ( $\tau_{\text{CH}_4}$  increases) if we exclude  $\text{NO}_x$  emission from soils. To investigate whether other surface  $\text{NO}_x$  emissions result in similar effects, or if they differ due to differences in their distribution, we performed a third simulation (REDOTHER) in which we reduced the  $\text{NO}_x$  emission from all other sources by the same amount as is emitted by the soils.

In the following section we briefly describe the model setup. We then compare the relevant tracer mixing ratios from the BASE simulation versus the NOBIONO and REDOTHER simulations. In the final section we present our conclusions and outlook.

## 2 Model description and setup

### 2.1 General

For this study the Modular Earth Submodel System version 1.6 (MESSy) coupled to the general circulation model ECHAM5 is employed. MESSy connects, through a standardized interface, submodels for different processes with bidirectional feedbacks (Jöckel et al., 2005, 2006). The combined system is referred to as the ECHAM5/MESSy atmospheric chemistry (EMAC) model. The meteorology for these simulations is driven by sea surface temperature (SST) from the AMIPiIb dataset (Taylor et al., 2000). The calculation of SNO<sub>x</sub> in the BASE simulation is based on the algorithm of Yienger and Levy II (1995), which is the most widely used SNO<sub>x</sub> algorithm in CTMs (Ganzeveld et al., 2002a; Jaeglé et al., 2005; Delon et al., 2008). This calculation is performed in the submodel ONLEM (Kerkweg et al., 2006b).  $\text{NO}_x$  produced by lightning is calculated in the submodel LNOX ( $1.6 \text{ Tg(N) yr}^{-1}$ ). The remaining sources of  $\text{NO}_x$  ( $43.5 \text{ Tg(N) yr}^{-1}$ ) are read in from the offline EDGAR database (Olivier et al., 1994) by the submodel OFFLEM (Kerkweg et al., 2006b). NO emission from fossil fuel combustion, biomass and biofuel burning are combined and account for  $43 \text{ Tg(N) yr}^{-1}$ , while aircraft emit only  $0.6 \text{ Tg(N) yr}^{-1}$ . Other relevant emissions are calculated either by the ONLEM or OFFLEM submodel.

A model spinup time of eleven months (January–November 1994) was chosen and the data of the period December 1994–December 1995 is analyzed here. To achieve an identical meteorology of both simulations feedback through trace gases and water vapor is switched off. Table 1 recapitulates the setup of the two simulations.

In the BASE simulation a yearly emission flux of  $9.7 \text{ Tg(N)}$  was calculated. In the REDOTHER simulation the offline surface NO emission ( $43 \text{ Tg(N) yr}^{-1}$ ) are reduced globally by 22.5%, which corresponds to  $9.7 \text{ Tg(N) yr}^{-1}$ .

### 2.2 Soil NO emission algorithm

The emission of NO from soils is calculated based on the algorithm developed by Yienger and Levy II (1995) and

depends on ecosystem type, soil moisture state and the surface temperature. Our underlying ecosystem map is compiled from Olson (1992) (Ganzeveld et al., 2006), which 72 ecosystem classes have been reduced to the twelve ecosystems defined by Yienger and Levy II (1995), with corresponding dry and wet emission factors (Table 2). Agriculture and (tropical) rainforest is treated separately. In the original algorithm the precipitation history is used to distinguish between the dry and wet soil moisture state. In our implementation we define the dry state to be when the soil moisture is below 10% volumetric soil moisture and wet above 10%. The temperature dependence is calculated according to Eq. (1) for wet soil conditions and (2) for dry soil conditions.

$$F_{\text{NO}}(T, A_w) = \begin{cases} 0, 28 \cdot T \cdot A_w & 0^\circ\text{C} < T \leq 10^\circ\text{C} \\ e^{0.103 \cdot T} \cdot A_w & 10^\circ\text{C} < T \leq 30^\circ\text{C} \\ 21, 97 \cdot A_w & T > 30^\circ\text{C} \end{cases} \quad (1)$$

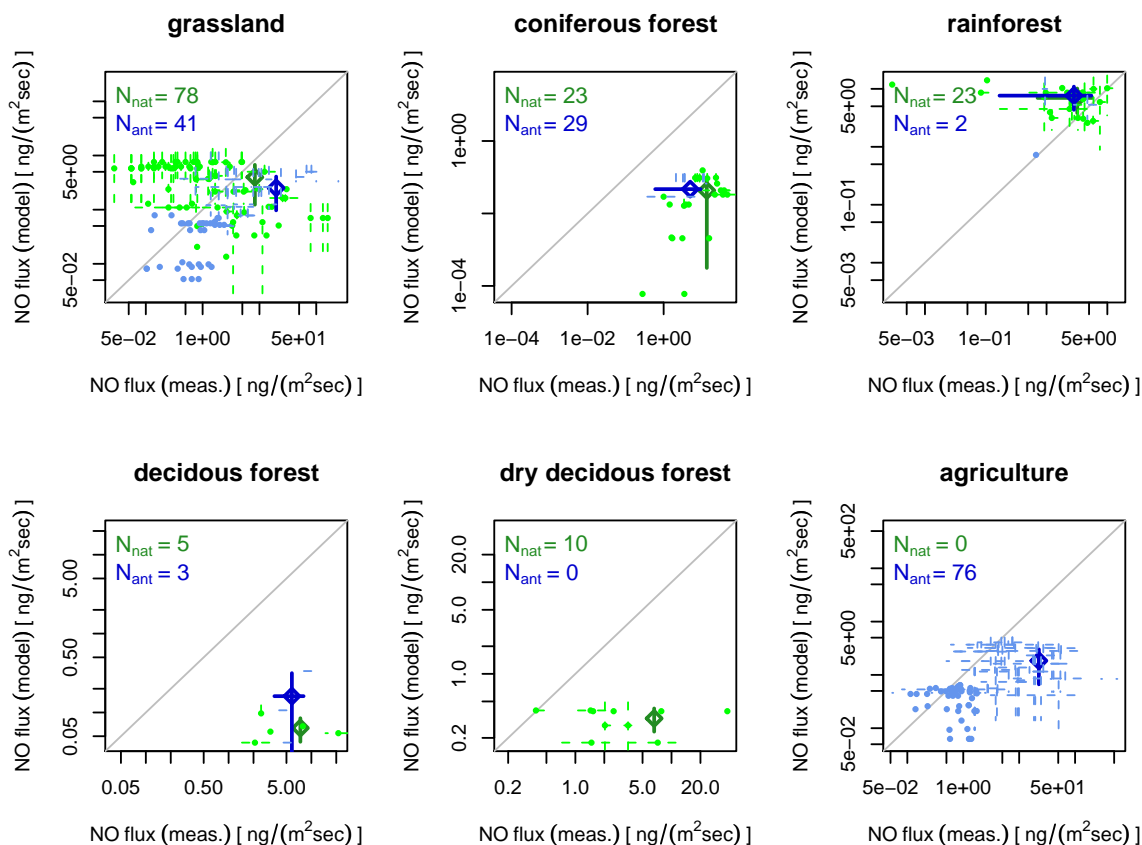

$$F_{\text{NO}}(T, A_d) = \begin{cases} \frac{T}{30} \cdot A_d & 0^\circ\text{C} < T \leq 30^\circ\text{C} \\ A_d & T > 30^\circ\text{C} \end{cases} \quad (2)$$

In the rainforest Yienger and Levy II (1995) assumed SNO<sub>x</sub> to be constant: a dry emission factor is applied for the five driest months (Northern Hemisphere: May–September, Southern Hemisphere: November–March) and a wet emission factor for the remaining seven months. For agricultural areas wet grassland conditions are assumed for the whole year. On top of that, fertilizer induced emission based on Bouwman and Boumans (2002) is added.

**Table 2.** Ecosystems and emission factors according to Yienger and Levy II (1995).

Ecosystem	emission factor	
	wet $A_{w,e}$	dry $A_{d,e}$
1 water	0	0
2 ice	0	0
3 desert	0	0
4 scrubland	0	0
5 tundra	0.05	0.37
6 grassland	0.36	2.65
7 woodland	0.17	1.44
8 deciduous forest	0.03	0.22
9 coniferous forest	0.03	0.22
10 dry deciduous forest	0.06	0.4
11 rainforest	2.6	8.6
12 agriculture	0	0

If, after a certain period of dryness, the soil receives a sufficient amount of precipitation a burst of NO emission occurs. Based on the precipitation history of the last 14 days and if the soil moisture state is defined as dry, this burst is implemented as pulsing factor, depending on the amount of precipitation during the last day (Eq. 3) and lasting for  $d$  days.

**Fig. 1.** Scatterplots of measured versus modeled NO emission flux from soils in different ecosystems. Measurements under natural conditions are colored in green and anthropogenically influenced measurements are in blue, mean and standard deviation slightly darker.

If this pulse is not active, the pulsing factor equals one.

$$\text{pulse} = \begin{cases} 11, 19 \cdot e^{-0,805 \cdot d} & 1 < d < 3; \quad 1-5 \frac{\text{mm}}{\text{day}} \\ 14, 68 \cdot e^{-0,384 \cdot d} & 1 < d < 7; \quad 5-15 \frac{\text{mm}}{\text{day}} \\ 18, 46 \cdot e^{-0,208 \cdot d} & 1 < d < 14; \quad > 15 \frac{\text{mm}}{\text{day}} \end{cases} \quad (3)$$

This is the direct modeled SNO<sub>x</sub>. Within the vegetation layer the NO emitted by the soil rapidly reacts to NO<sub>2</sub> and is partly deposited back on the vegetation and the ground. This is reflected by the canopy reduction factor (CRF,  $0 \leq \text{CRF} \leq 1$ ), calculated depending on the leaf area index (LAI) and the stomatal area index (SAI).

The NO flux reaching the atmosphere is therefore calculated as:

$$\text{flux} = \text{CRF} \cdot \text{pulse} \cdot F_{\text{NO}}(T, A_{d/w}) \quad (4)$$

We have made a preliminary comparison of the model simulated soil NO emissions versus measurements for the period 1990 to 2000 without canopy reduction (Steinkamp, 2007). Figure 1 shows an overview of these comparisons. We found that the yearly averaged flux in the tropics compares well with measurements, whereas the fluxes in temperate regions seem to be underestimated. Since the applied algorithm is

empirically based, comparison on a point by point basis are not appropriate, but the overall distribution can be compared, in general the emission flux tends to be underestimated in all ecosystems, except for the rainforest.

### 3 Results and discussion

The emissions of NO from soils in the BASE simulation accounts for 18% of the total annual global NO emissions (Table 3). The interannual variability of SNO<sub>x</sub> is low in the model (Steinkamp, 2007). The largest SNO<sub>x</sub> emissions are calculated for tropical regions. During JJA there are some exceptions further north in Northern America, Europe and North-Eastern China. These are fertilizer induced emissions in agricultural regions (Fig. 2 and Table 3).

The data is analyzed by season with a focus on the winter and summer season. There is a notable seasonal variation with larger SNO<sub>x</sub> in the summer period of each hemisphere and with a larger contribution of SNO<sub>x</sub> to the total NO emissions during the northern hemispheric spring and summer (Table 3). The first point can be explained by the temperature dependence of SNO<sub>x</sub> and the second one by the greater landmasses in the Northern Hemisphere. In the

northern mid-latitudes SNO<sub>x</sub> plays a less important role relative to other NO<sub>x</sub> emissions, except during the JJA period.

### 3.1 Influence of NO emissions on related trace gases

The column mean mixing ratios of NO<sub>x</sub>, PAN, HNO<sub>3</sub> and O<sub>3</sub> and the column mean concentration of OH in the gridcells (weighted by the air mass in the gridcells) in the lower troposphere (below 500 hPa; hereafter “LT”) from the BASE simulation are compared with the values from the NOBIONO and REDOTHER simulations in this section. Here we first consider the overall correlations between the changes in the trace gas columns and the SNO<sub>x</sub> distribution (Table 4), then we discuss the changes in the individual gases in the following subsections.

As expected, in the surface layer (hereafter “SL”) as well as in the LT the difference between the NO<sub>x</sub> column mean mixing ratio in the NOBIONO simulation versus the BASE simulation is well-correlated with SNO<sub>x</sub> in all regions (Table 4; scatterplots are included in the supplement <http://www.atmos-chem-phys.net/9/2663/2009/acp-9-2663-2009-supplement.pdf>). A low correlation is computed for the Northern Hemisphere LT during DJF, as expected due to the small SNO<sub>x</sub> compared to the anthropogenic emissions.

There is hardly any correlation in the low-latitudes and in the northern mid-latitudes of SNO<sub>x</sub> and the difference in the column mean mixing ratio of PAN in the two simulations (Table 4). In contrast, there is a better correlation in the southern mid-latitudes between the difference in the LT PAN column mixing ratio and SNO<sub>x</sub>. This suggests a dominating role of SNO<sub>x</sub> in the formation of PAN in the mid-latitudes of the Southern Hemisphere. The other precursor of PAN, peroxyacyl radicals, depend on the photooxidation of VOCs, which in turn depends on O<sub>3</sub> and OH (Roberts et al., 2001; Cleary et al., 2007). At low latitudes, convective updrafts and subsiding airmasses, combined with the strong temperature dependence of the decomposition of PAN decreases the correlation.

**Fig. 2.** Simulated SNO<sub>x</sub> flux for (a) December 1994 to February 1995 and (b) June to August 1995 in  $\frac{\text{ng}}{\text{m}^2 \text{ sec}}$ .

The correlation between SNO<sub>x</sub> and the difference in the LT O<sub>3</sub> column mean mixing ratio is lower than for NO<sub>x</sub>. This is partly due to the longer lifetime of O<sub>3</sub>, which is better mixed in the LT. Furthermore the production of O<sub>3</sub> is not only determined by the NO<sub>x</sub> mixing ratio, but also by the concentration of VOC. The correlation of the OH column mean concentration difference in the LT with SNO<sub>x</sub> is similar to O<sub>3</sub>. OH is a very short lived tracer, whose production depends mainly on: 1.) the photolysis of O<sub>3</sub> and the water vapor concentration in the lower troposphere, 2.) the reaction of NO with HO<sub>2</sub> in the upper troposphere and 3.) the reaction of O<sub>3</sub> with HO<sub>2</sub> (Fig. 3). This results, depending on the dominating reaction, in a higher or lower correlation of the OH column concentration difference versus SNO<sub>x</sub> than the

**Table 4.** Correlation coefficient ( $R^2$ ) between surface SNO<sub>x</sub> flux values and the difference (NOBIONO-BASE) of the tracer burden in the overlying model surface layer (SL) lower troposphere (LT; >500 hPa) by gridcell, averaged over the corresponding period; only gridcells with a land surface fraction of at least 75% were included.

correlation for the O<sub>3</sub> column mixing ratio difference versus SNO<sub>x</sub>. The correlation of the changes in the mixing ratios of O<sub>3</sub> and OH versus SNO<sub>x</sub> is lower in the SL than in the LT. Due to the longer lifetime of O<sub>3</sub> compared to NO<sub>x</sub>, the O<sub>3</sub> distribution depends more on transport away from the source regions. The horizontal transport explains the lower correlation compared to NO<sub>x</sub> and vertical transport can explain the higher correlation in the column compared to the SL.

### 3.1.1 NO<sub>x</sub>

The global mean mixing ratio of NO<sub>x</sub> in the LT during DJF decreases by 7% in the NOBIONO simulation compared to the BASE simulation. During JJA it decreases by 17%. In both cases the decrease in the mixing ratio is less than the contribution of SNO<sub>x</sub> (14% and 23%, respectively). The maximum decrease is 81% in DJF and 78% in JJA, while the maximum absolute decreases in the DJF and JJA periods are 365 and 319 pmol mol<sup>-1</sup>, re-

spectively (figures with absolute differences can be found in the supplement <http://www.atmos-chem-phys.net/9/2663/2009/acp-9-2663-2009-supplement.pdf>). Interestingly, during DJF the mixing ratio above large parts of the Northern Hemisphere increases, by up to 7% (Fig. 4a) in the NOBIONO simulation, with the largest absolute increase of 12.3 pmol mol<sup>-1</sup> above Europe. In the JJA period the maximum relative increase of 7.6% is larger than in the DJF period, but the maximum absolute difference is only 7.0 pmol mol<sup>-1</sup> (Fig. 4b).

A similar result has been noted for model sensitivity simulations with and without NO<sub>x</sub> from lightning (Stockwell et al., 1999; Labrador et al., 2005), in which a decrease in near-surface NO<sub>x</sub> mixing ratios was computed for similar regions with increasing production of NO<sub>x</sub> by lightning. Although NO<sub>x</sub> produced by lightning is formed in the free troposphere and SNO<sub>x</sub> originates from the surface, we achieve comparable results with SNO<sub>x</sub> as with lightning NO<sub>x</sub> by

**Fig. 3.** Zonal mean relative contribution of the eight major OH producing reactions in the BASE simulation integrated over one year.

Labrador et al. (2005). To explain why the  $\text{NO}_x$  mixing ratio decreases less than the relative decrease in the emission of the NOBIONO simulation compared to the BASE simulation, and why it even increases during the DJF period in large areas in the Northern Hemisphere, the feedback through  $\text{O}_3$  and OH has to be taken into account. Stockwell et al. (1999) assumed that the general increase in  $\text{O}_3$  with lightning  $\text{NO}_x$  causes an increase in OH. This OH reduces the lifetime of  $\text{NO}_x$  ( $\tau_{\text{NO}_x}$ ) through Reaction (R1) above regions with high non-lightning  $\text{NO}_x$  sources. Labrador et al. (2005) showed that the conversion to  $\text{HNO}_3$  via  $\text{N}_2\text{O}_5$  also contributes to the shorter  $\tau_{\text{NO}_x}$  (Reaction R2) with higher  $\text{NO}_x$  emissions.

Similarly we find that without SNO<sub>x</sub>,  $\text{O}_3$  and OH levels decrease over large regions due to the longer  $\text{O}_3$  lifetime, resulting in enhanced  $\tau_{\text{NO}_x}$ , and due to Reactions (R1) and (R2) the  $\text{NO}_x$  mixing ratio increases in some regions with low SNO<sub>x</sub>. The changes in  $\text{HNO}_3$ ,  $\text{O}_3$  and OH related to this are discussed in the following sections.

**Fig. 4.** Relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the lower tropospheric mixing ratio of NO<sub>x</sub> in % (regions with values below 30 pmol mol<sup>-1</sup> in the BASE simulation are excluded from the calculation) averaged for (a) December, January, February and (b) June, July and August.

In the vertical direction the strongest effects of SNO<sub>x</sub> are simulated near the surface (DJF: 59%, JJA: 55%), and a decrease of up to 10 to 25% at higher altitudes in the zonal mean is calculated when SNO<sub>x</sub> is switched off (Fig. 5). The effect of convective transport to higher altitudes has a stronger influence on the difference in the total burden between 500 and 250 hPa during DJF (relative: 11.3%, absolute: 1.6 Gg) than during JJA (relative: 9.0%, absolute: 1.1 Gg). This is because the main regions where the convective transport is most effective are in the Southern Hemisphere, especially the Amazon Basin and the southern tropics of Africa (not shown). In the REDOTHER simulation the relative decrease between 500 and 250 hPa is much smaller (DJF: 5.2%, JJA: 2.9%).

The reduction of all remaining surface emissions in the REDOTHER simulation leads to a decrease in the LT NO<sub>x</sub> mixing ratio of 19% during DJF and 12% during JJA compared to the BASE simulation. A small relative increase, by less than 1%, occurs only in oceanic regions where the absolute mixing ratio is below 30 pmol mol<sup>-1</sup>. The main decreases are located above the (northern hemispheric) land surfaces (Fig. 6). In the zonal mean the maximum extent of the relative decrease is located closer to the surface, because the major changes are outside the tropics and are not lifted as effectively by deep convection (Fig. 7).

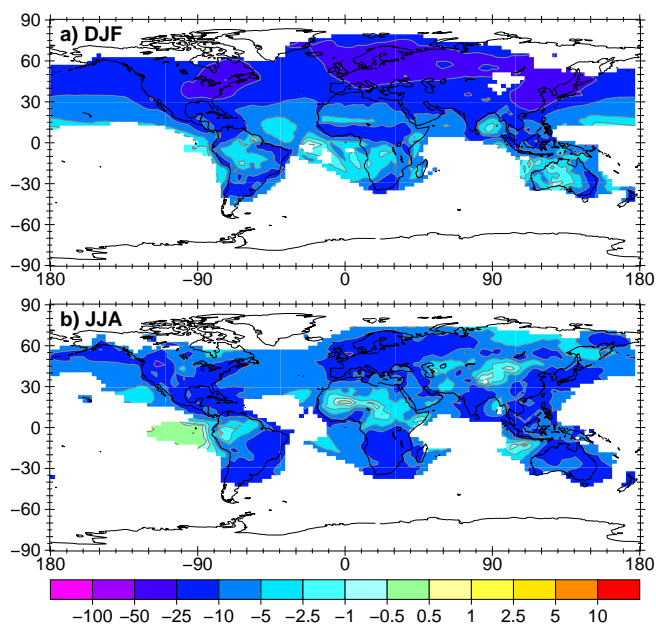

**Fig. 5.** Zonal mean relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the NO<sub>x</sub> mixing ratio in % averaged for (a) December, January, February and (b) June, July and August. Note that the y-axis is linearly scaled, since the focus of this work lies in the lower troposphere.

### 3.1.2 PAN

The LT PAN mixing ratio decreases globally by 4% during DJF and 10% during JJA without SNO<sub>x</sub>. In both periods the PAN mixing ratio decreases nearly everywhere above the continents (Fig. 8). Above the tropical oceans, especially during JJA, there is a high relative but a negligible absolute increase in the PAN mixing ratio associated with a decrease in SNO<sub>x</sub>. As mentioned above, the formation of PAN in the northern mid- and low latitudes relies more on other trace gases than on SNO<sub>x</sub>, but more on SNO<sub>x</sub> in the southern mid-latitudes. This explains the larger decrease during DJF than during JJA. There is also no increase of PAN in the Northern Hemisphere during DJF despite higher NO<sub>x</sub> mixing ratios, which confirms a dominating role of VOC in PAN formation.

Interestingly, in the upper troposphere between 500 hPa and 250 hPa the largest decrease in the PAN mixing ratio is during DJF (6.5%), whereas it is 5.1% during JJA. In the zonal mean of the relative difference in PAN mixing ratio with and without SNO<sub>x</sub> (Fig. 9), the effect of convective transport in the lower latitudes is more effective during DJF than during JJA. At the higher altitudes PAN does not increase anymore, due to its longer lifetime resulting in better mixing. In the REDOTHER simulation the decrease (DJF: 4.1%, JJA: 1.4%) is smaller between 500 and 250 hPa.

**Fig. 6.** Relative difference ( $\frac{\text{REDOTER}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the lower tropospheric mixing ratio of  $\text{NO}_x$  in % (regions with values below  $30 \text{ pmol mol}^{-1}$  in the BASE simulation are excluded from the calculation) averaged for (a) December, January, February and (b) June, July and August.

The differences in the PAN mixing ratio should be interpreted with caution, because the model generally overestimates its levels compared to observations (Jöckel et al., 2006), though this may improve with a new isoprene oxidation scheme (Taraborrelli et al., 2008).

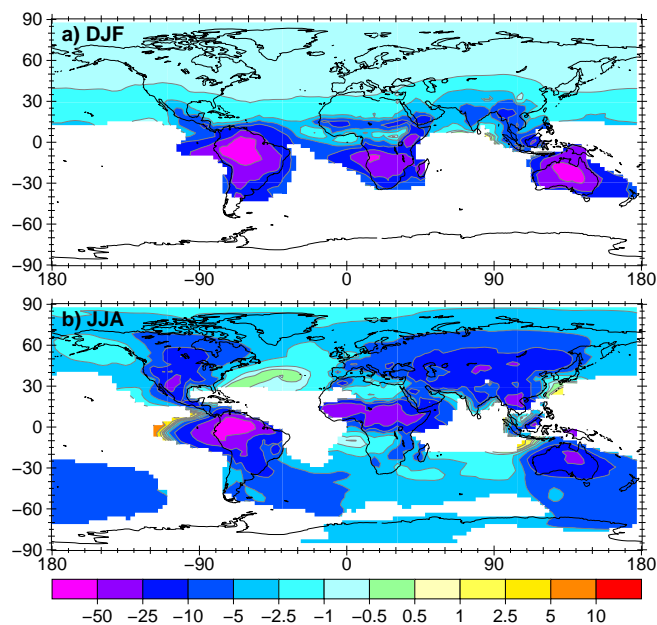

### 3.1.3 $\text{HNO}_3$

The global LT mean mixing ratio of  $\text{HNO}_3$  decreases by 15% (DJF) and 19% (JJA) without SNOx. The greatest decrease occurs above continental regions of the low-latitudes and in the summer months in the Northern Hemisphere (Fig. 10). The amplified decrease in the mixing ratio of  $\text{HNO}_3$  compared to the decrease of  $\text{NO}_x$  mixing ratio is because the formation of  $\text{HNO}_3$  is not only determined by the  $\text{NO}_x$  mixing ratio, but also relies on the mixing ratios of  $\text{O}_3$  and OH, which also decrease, as discussed in the following sections.

Nitric acid is mainly deposited on aerosol particles, taken up by cloud water or directly deposited on the earth's surface. The deposition of  $\text{HNO}_3$  is decreased by 18% throughout the year without SNOx. During DJF the decrease is 15% and during JJA it is 25%. In the REDOTER simulation the deposition decrease does not substantially change during the year (18%, DJF: 19%, JJA: 17%).

**Fig. 7.** Zonal mean relative difference ( $\frac{\text{REDOTER}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the  $\text{NO}_x$  mixing ratio in % averaged for (a) December, January, February and (b) June, July and August.

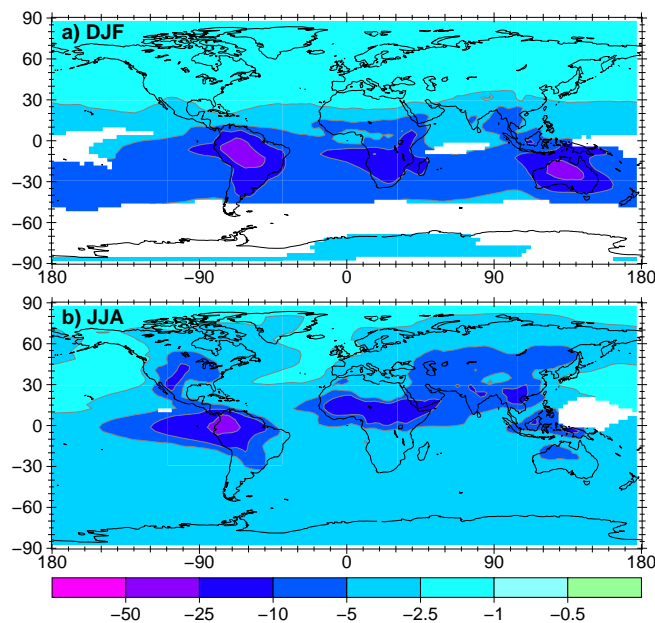

**Fig. 8.** Relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the lower tropospheric mixing ratio of PAN in % (regions with values below  $50 \text{ pmol mol}^{-1}$  in the BASE run are excluded from the calculation) averaged for (a) December, January, February and (b) June, July and August.

**Fig. 9.** Zonal mean relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the PAN mixing ratio in % averaged for (a) December, January, February and (b) June, July and August.

**Fig. 10.** Relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the lower tropospheric mixing ratio of  $\text{HNO}_3$  in % (region with values below  $30 \text{ pmol mol}^{-1}$  in the BASE simulation are excluded from the calculation) averaged for (a) December, January, February and (b) June, July and August.

**Fig. 11.** Relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the lower tropospheric mixing ratio of  $\text{O}_3$  in % (regions with values below  $25 \text{ nmol mol}^{-1}$  in the BASE simulation are excluded from the calculation) averaged for (a) December, January, February and (b) June, July and August.

### 3.1.4 $\text{O}_3$

The mixing ratio of  $\text{O}_3$  in the NOBIONO simulation compared to the BASE simulation decreases by 5% in the LT during both seasons, with the greatest decline above the continents (Fig. 11). The maximum relative decrease during DJF is 38% and during JJA it is 33%. The maximum absolute decrease ( $16.2 \text{ nmol mol}^{-1}$ ) occurs during DJF above Australia (Fig. 11a). In contrast to what was found for  $\text{NO}_x$ , there is no region with increasing  $\text{O}_3$  mixing ratios. The removal of  $\text{SNO}_x$  is less effective in reducing the  $\text{O}_3$  mixing ratio during JJA (17%) than during DJF (7%). This is because the formation of  $\text{O}_3$  through  $\text{SNO}_x$  competes with other strong sources of  $\text{NO}_x$  during JJA in the Northern Hemisphere, whereas  $\text{SNO}_x$  is relatively much more important the formation of  $\text{O}_3$  during DJF in the Southern Hemisphere. Furthermore, as was noted above for the PAN formation in the Northern Hemisphere the simulated  $\text{O}_3$  production depends more on VOC and other  $\text{NO}_x$  sources than  $\text{SNO}_x$ , Beekmann and Vautard (2009) show for example different photochemical regimes in Europe.

In the zonal mean distribution (not shown) a similar pattern of the influence of convection can be seen as already discussed for  $\text{NO}_x$  and PAN. But due to the longer lifetime of  $\text{O}_3$  the relative change is a maximum decrease of 13% (DJF) and 10% (JJA), which is not as strong and is more evenly distributed above all latitudes, as well as in the vertical direction. In the zonal mean there is, as with the horizontal, no region in which the mean  $\text{O}_3$  mixing ratio increases.

**Fig. 12.** Relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the lower tropospheric concentration of OH in % (regions with values below  $10^4$  molec  $\text{cm}^{-3}$  in the BASE simulation are excluded from the calculation) averaged for (a) December, January, February and (b) June, July and August.

Interestingly, in contrast to these results for SNO<sub>x</sub>, in the REDOTHER simulation the mean LT O<sub>3</sub> mixing ratio only decreases by 2.7% (DJF) and 1.8% (JJA). In the zonal mean the increase does not exceed 5%.

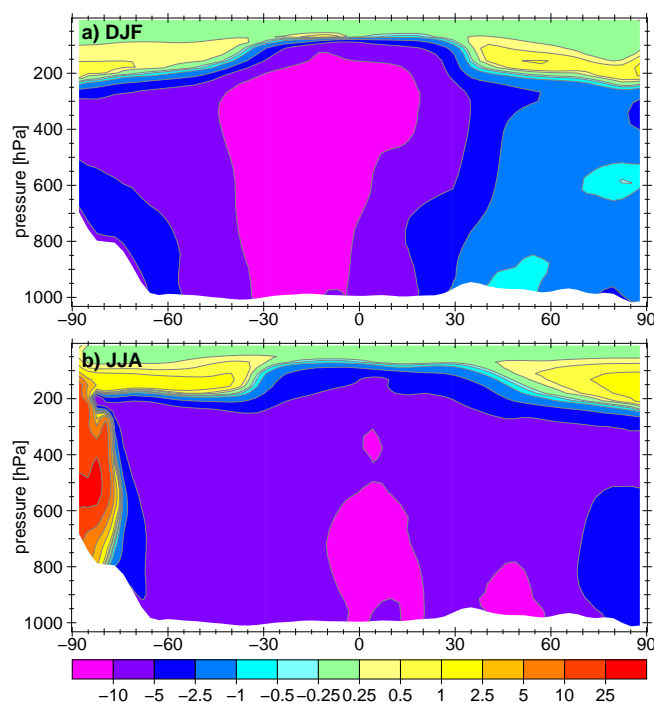

### 3.1.5 OH

When we exclude the contribution of SNO<sub>x</sub>, the mean LT OH concentration decreases by 10% during DJF and 9% during JJA. The largest relative decrease is 65% during DJF and 62% during JJA above the tropical land regions. During DJF the decrease is shifted to the southern tropics and to the northern tropics during JJA (Fig. 12). Note that during JJA an absolute increase above the Antarctic region is calculated, but the OH concentration here is less than  $1 \times 10^4$  molec  $\text{cm}^{-3}$ .

The decrease is in part induced directly by NO<sub>x</sub> through Eq. (R3), and in part indirectly by the lower O<sub>3</sub> mixing ratio, leading to less primary OH production, and therefore to a decrease of the OH concentration in the LT.

The largest relative decrease in the zonal mean concentration of OH is 19% during DJF and 16% during JJA. This maximum of the relative decrease in the OH concentration without SNO<sub>x</sub> is nearly detached from the surface, despite the surface source of SNO<sub>x</sub> (Fig. 13). At the surface OH production is mainly related to the reaction of O(<sup>1</sup>D) with water,

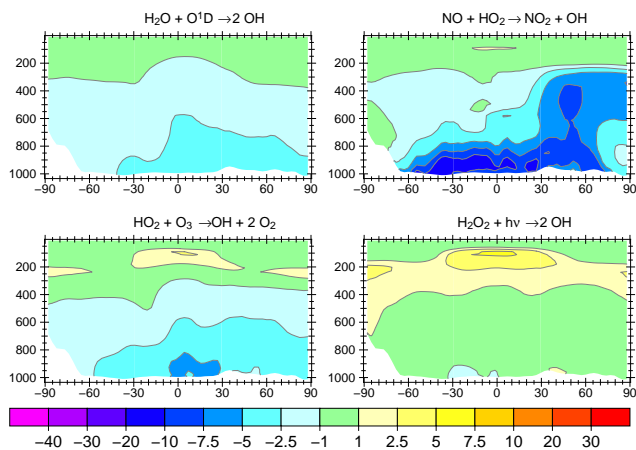

**Fig. 13.** Zonal mean relative difference ( $\frac{\text{NOBIONO}-\text{BASE}}{\text{BASE}} * 100\%$ ) of the OH concentration in % averaged for (a) December, January, February and (b) June, July and August.

**Fig. 14.** Zonal mean relative change in the OH production of the four major OH producing reactions in the NOBIONO simulation compared to the BASE simulation over one year.

while at higher altitudes it depends more on the reaction of NO with HO<sub>2</sub> (Eq. R3, see also Fig. 3). In the zonal mean the shift to the Southern Hemisphere during DJF is stronger than the shift during JJA to the Northern Hemisphere. The major driving reactions for the absolute decrease are the reaction of H<sub>2</sub>O with O(<sup>1</sup>D), reaction R3, and HO<sub>2</sub> with O<sub>3</sub> and photolysis of H<sub>2</sub>O<sub>2</sub>. The relative contribution of the four major OH producing reactions shows their strongest decrease in the

**Fig. 15.** Zonal mean relative change in the OH production of the four major OH producing reactions in the REDOTHER simulation compared to the BASE simulation over one year.

**Fig. 16.** Seasonal cycle of monthly mean lifetime of  $\text{CH}_4$  from December 1994 to December 1995 in years (calculated according to Lawrence et al., 2001).

lower latitudes throughout the year for the NOBIONO simulation (Fig. 14), whereas the the largest changes in the REDOTHER simulation are located much closer to the surface (Fig. 15) and are not as large as in the NOBIONO simulation.

In the REDOTHER simulation, with a 4% decrease during both seasons in the LT, the region with the strongest decrease is always located over the Northern Hemisphere and the maximum relative decreases are only 15% and 11%, respectively.

### 3.1.6 Summary for the trace gases

By following the reaction chain from  $\text{NO}_x$  through  $\text{O}_3$  and OH, including the branches of  $\text{HNO}_3$  and PAN, the correlation of the change in the mixing ratio between the BASE

**Fig. 17.** Relative increase of  $\tau_{\text{CH}_4}$  ( $\frac{\tau_{\text{CH}_4, \text{simulation}} - \tau_{\text{CH}_4, \text{BASE}}}{\tau_{\text{CH}_4, \text{BASE}}} * 100\%$ ) for the NOBIONO (red) and REDOTHER (blue) simulation in various zonal subdomains of the atmosphere (calculated according to Lawrence et al., 2001).

and NOBIONO simulation with the  $\text{SNO}_x$  source declines. The strongest correlations can be found in the southern hemispheric mid-latitudes, which indicates an important role of  $\text{SNO}_x$  in that region.

Although the total  $\text{NO}_x$  emission decreases in the NOBIONO simulation, we simulate an increase in the LT  $\text{NO}_x$  mixing ratio during DJF in the Northern Hemisphere. When reducing the other surface  $\text{NO}_x$  emissions in the REDOTHER simulation, we did not see an increase in the mixing ratio. This is because the influence on the  $\text{O}_3$  and OH mixing ratios in the NOBIONO simulation is stronger than for the REDOTHER simulation and the feedback on  $\tau_{\text{NO}_x}$  is not strong enough in the REDOTHER simulation to increase the mixing ratio with reduced surface  $\text{NO}_x$  emissions. Our results suggest that  $\text{SNO}_x$  has a stronger influence on the related chemical processes than the remaining  $\text{NO}_x$  sources due to the geographical distribution.

### 3.2 Influence of $\text{SNO}_x$ on the oxidizing efficiency

The oxidation of CO and VOC in the atmosphere is mainly driven by OH. As a measure for the oxidizing efficiency of the atmosphere,  $\tau_{\text{CH}_4}$  is calculated for all simulations according to Lawrence et al. (2001). The trend of monthly mean values is depicted in Fig. 16. The mean  $\tau_{\text{CH}_4}$  averaged for one year (December 1994 to November 1995) for the BASE simulation is 7.25 years. It is 7.96 years in the NOBIONO simulation, a 9.8% increase without  $\text{SNO}_x$  and 7.6 years (a 4% increase) for the REDOTHER simulation. The maximum prolongation of 0.97 years (12%) occurs in February 1995 for the NOBIONO simulation and 0.38 years (4%) in December 1994 for the REDOTHER simulation.

The changes in  $\tau_{\text{CH}_4}$  are not equally distributed over the globe. In the Southern Hemisphere and low-latitudes the relative influence is noticeably greater than in the northern

latitudes for the NOBIONO simulation (Fig. 17). This agrees with the smaller relative change in the OH concentration in the northern latitudes (Fig. 12). In the zonal mean, the relative changes are slightly larger above 500 hPa for the NOBIONO simulation, despite the origin of SNO<sub>x</sub> at the surface. Beginning from the surface source of SNO<sub>x</sub> and following the reaction chain from NO<sub>x</sub> over O<sub>3</sub> and OH in each step, the relative difference of our two simulations becomes smaller near the surface and larger at higher altitudes. This trend corroborates the larger relative change of the oxidizing efficiency at higher altitudes. However, only ~15% of the absolute amount of CH<sub>4</sub> in the troposphere is oxidized above 500 hPa (Lawrence et al., 2001).

Labrador et al. (2004) modelled a decrease of 15% in  $\tau_{\text{CH}_4}$  in a simulation with 5 Tg(N) NO<sub>x</sub> produced by lightning relative to one with no lightning NO<sub>x</sub>. Compared to this, SNO<sub>x</sub> is somewhat less effective in altering the oxidizing efficiency of the atmosphere, which is interesting, given that CH<sub>4</sub> oxidation is more effective near the surface where SNO<sub>x</sub> is emitted, due to the strong temperature dependence of the reaction of OH with CH<sub>4</sub>. The change in the oxidizing efficiency due to lightning NO<sub>x</sub> is larger than due to SNO<sub>x</sub>, even though the total emission rate is lower. This is because at higher altitudes the NO:NO<sub>2</sub> ratio is greater, so that with more NO the NO<sub>x</sub> lifetime is not diminished as strongly as near the surface. Furthermore at higher altitudes more NO results in higher OH yields by reaction with HO<sub>2</sub>.

#### 4 Conclusions and outlook

The emission of NO from soils plays an important role for chemical reactions in the atmosphere in our simulations. Lower global mean NO<sub>x</sub> mixing ratios without SNO<sub>x</sub> lead to lower global O<sub>3</sub> mixing ratios in the LT. The lower O<sub>3</sub> mixing ratios result in lower OH concentrations. This results in an enhanced lifetime of NO<sub>x</sub> in regions with other dominating sources of NO<sub>x</sub>. Hence the NO<sub>x</sub> mixing ratios increases in some regions, despite lower emissions when SNO<sub>x</sub> is neglected in our NOBIONO simulation. This effect did not occur in the REDOTHER simulation, in which we comparably reduced the remaining surface NO emissions. From this it follows that although NO<sub>x</sub> is a short-lived tracer it indirectly influences chemical processes in regions with low SNO<sub>x</sub> through feedback with O<sub>3</sub> and OH. By following the reaction chain up to PAN and HNO<sub>3</sub>, we detected a dominating role of SNO<sub>x</sub> compared to VOC in the mid-latitudes of the Southern Hemisphere. Also by following the reaction chain (SNO<sub>x</sub>→NO<sub>x</sub>→O<sub>3</sub>→OH), the magnitude of relative effects are shifted step by step to higher altitudes in the troposphere.

Through reaction of NO with HO<sub>2</sub>, SNO<sub>x</sub> is directly involved in the production of OH. SNO<sub>x</sub> also has, through O<sub>3</sub>, an indirect influence on OH production. With OH formed by SNO<sub>x</sub> through these pathways,  $\tau_{\text{CH}_4}$  is decreased consider-

ably, and the influence of SNO<sub>x</sub> on the tropospheric oxidizing efficiency is considerable, approximately 10%. Reducing the other surface NO emissions by the same amount only lead to an increase of 4% in  $\tau_{\text{CH}_4}$ .

The notable modelled influence of SNO<sub>x</sub> on directly and indirectly related trace gases shown in this work supports further efforts to improve the parameterization of SNO<sub>x</sub> in CTMs, as also proposed by Jaeglé et al. (2005).
